(Dated: December 23, 2008)

The inner crust of neutron stars, formed of a crystal lattice of nuclear clusters immersed in a sea of unbound neutrons, may be the unique example of periodic nuclear systems. We have calculated the neutron specific heat in the shallow part of the crust using the band theory of solids with Skyrme nucleon-nucleon interactions. We have also tested the validity of various approximations. We have found that the neutron specific heat is well described by that of a Fermi gas, while the motion of the unbound neutrons is strongly affected by the nuclear lattice. These apparently contradictory results are explained by the particular properties of the neutron Fermi surface.

Keywords: neutron star crust, neutron star cooling, band theory, specific heat, dynamical effective mass

Neutron stars are born in the gravitational core collapse of massive stars. With about one or twice the mass of the Sun compressed inside a radius of only 10 kilometers or so, neutron stars are among the most compact objects in the Universe [1]. The outer layers of the star, at densities below the neutron drip threshold $\rho_{\text{ND}} \simeq 4 \times 10^{11} \text{ g.cm}^{-3}$, are formed of a solid Coulomb lattice of neutron rich nuclei coexisting with a degenerate gas of relativistic electrons. The inner crust, at density above ρ_{ND} and below the crust-core transition density, which is at about half the density $\rho_0 = 2.8 \times 10^{14} \text{ g.cm}^{-3}$ inside atomic nuclei, is permeated by a sea of unbound neutrons, which could be superfluid in some layers [2].

Many observed neutron star phenomena are intimately related to the physics of the crust. For instance, X-ray bursts in Low-Mass X-ray Binaries are associated with thermonuclear burning in the accreting neutron star envelope [3]. In the subgroup of soft X-ray transients, accretion outbursts are followed by long period of quiescence during which the accretion rate is essentially zero. In some cases, the period of accretion can last long enough for the crust to be heated out of equilibrium with the core. The thermal relaxation during the quiescent state has been recently monitored for KS 1731–260 and for MXB 1659–29 after an accretion episode of 12.5 and 2.5 years respectively [5]. These observations thus provide information on the thermal properties of neutron star crusts [6, 7]. The thermal relaxation of the crust could also be potentially observed in very young isolated neutron stars, 10 – 100 years after their formation [8, 9].

The diffusion of heat in the inner crust is mainly governed by the thermal properties of the shallow layers, owing to their very low thermal diffusivity [9]. One of the key parameters is the neutron specific heat. In cooling simulations of neutron stars, the neutron specific heat is generally approximated by that of uniform neutron matter. At low enough temperatures, neutrons are predicted to become superfluid but the exact value of the critical

temperature T_c still remains uncertain [2]. Moreover, the presence of nuclear clusters is likely to modify the critical temperature. For instance, in Ref. [4], it has been shown that the pairing field in the dilute neutron gas completely vanishes just after the drip point.

The effects of superfluidity on the neutron specific heat are usually incorporated in the following way [10]:

$$c_V^{\text{paired}}(T) = \mathcal{R}(T/T_c) c_V(T) \quad (1)$$

where the renormalisation factor $\mathcal{R}(T/T_c)$ accounts for the effects of superfluidity and $c_V(T)$ stands for the specific heat calculated in the absence of superfluidity. In the above expression, the presence of the nuclear clusters is ignored. Their effects have been studied by solving the Hartree-Fock-Bogoliubov equations for the nucleons [11, 12] and by including the contribution of collective modes [13]. These calculations have been carried out within the spherical Wigner-Seitz approximation. However the validity of this approximation has been recently discussed [14]. Pointing out the analogy between unbound neutrons in neutron star crusts and conduction electrons in ordinary metals, the band theory of solids have been applied and adapted to the nuclear scale [15, 16]. It has shown for the first time the large effects of Bragg scattering on the motion of the unbound neutrons. One may expect that thermodynamical properties like the specific heat could also be modified.

In this paper, we investigate the effects of the solid crust on the neutron specific heat, within the framework of the nuclear band theory (Sec. I). Given the present uncertainties in the pairing problem, even in the simpler case of pure neutron matter [2], we will focus on the normal part $c_V(T)$ only. Results in the shallow layers are discussed in Sec. II and are compared to several approximations used in the literature.

I. A MICROSCOPIC MODEL OF THE NEUTRON STAR CRUST

Following the standard assumptions, we consider a body centered cubic crystal with only one nuclear cluster per lattice site [1]. We have taken the composition (N , Z) of the clusters calculated by Negele and Vautherin [17]. But the nucleon distributions have been recalculated at each temperature T by solving the finite temperature Hartree-Fock equations with the Skyrme SLy4 effective nucleon-nucleon interaction [18]. Typical temperatures of interest for cooling isolated neutron stars and for accreting neutron stars lie in the range between 10^7 to few 10^9 K [9].

Fully self-consistent calculations within the band theory are computationally very expensive. We have thus solved the Hartree-Fock equations in two steps [14]. First, we have determined self-consistently the nucleon distributions and mean fields in the Wigner-Seitz approximation with mixed Neumann-Dirichlet boundary conditions. We have removed the spurious fluctuations of the neutron density by averaging in the interstitial region [17]. In a second stage, we have solved the Schrödinger equation with Bloch boundary conditions using these self-consistent mean fields. We have fixed the lattice spacing so that the volume of the Wigner-Seitz polyhedron is equal to the volume of the spherical Wigner-Seitz cell of radius R_{cell} . We have employed the Linearized Augmented Plane Wave method described in details in Ref. [16]. As shown in Ref. [14], the one-body spin-orbit potential has a negligible effect on the neutron level ordering and was therefore neglected.

The specific heat (per unit volume) is defined as

$$c_V(T) = \left. \frac{\partial U}{\partial T} \right|_V = T \left. \frac{\partial S}{\partial T} \right|_V, \quad (2)$$

(taking the Boltzmann's constant $k_B = 1$) where U is the total internal energy density, S the entropy density and the partial derivatives are evaluated at constant volume V . We have found that the latter expression is numerically more convenient. The entropy density of the

TABLE I: For the three shallow layers considered in this paper, are given: the total density (ρ), the number of protons and neutrons (Z , N respectively), the nuclear mass number A (at $T = 0$), the radius of the cell (R_{cell}) and the neutron gas density at $T=0$ (ρ_n^G).

ρ [g.cm ⁻³]	Z	N	A	R_{cell} [fm]	ρ_n^G [fm ⁻³]
6.69×10^{11}	40	160	133	49.24	$1.3 \cdot 10^{-4}$
1.00×10^{12}	40	210	141	46.33	$2.6 \cdot 10^{-4}$
1.47×10^{12}	40	280	140	44.30	$4.9 \cdot 10^{-4}$

unbound neutrons is given by

$$S = - \sum_{\alpha} \int \frac{d^3 \mathbf{k}}{(2\pi^3)} \left[f_{\alpha \mathbf{k}} \ln f_{\alpha \mathbf{k}} + (1 - f_{\alpha \mathbf{k}}) \ln(1 - f_{\alpha \mathbf{k}}) \right] \quad (3)$$

where α is the band index, \mathbf{k} is the Bloch wave vector and $f_{\alpha \mathbf{k}}$ is the Fermi-Dirac distribution. The latter depends on the temperature and the neutron chemical potential μ_n which is determined from the total density ρ_n^G of unbound neutrons by

$$\rho_n^G = \sum_{\alpha} \int \frac{d^3 \mathbf{k}}{(2\pi^3)} f_{\alpha \mathbf{k}}. \quad (4)$$

Integrations have been carried out using the special point method (see [16]). Note that the number of unbound neutrons per cluster is determined by the shape of the mean fields, which vary with temperature. Consequently ρ_n^G can also depend on the temperature. In particular, with increasing temperature the most loosely bound neutrons may be excited into the delocalized states.

II. RESULTS AND DISCUSSIONS

We have considered three different layers in the shallow region of the inner crust. Their properties are summarized in Table I. The neutron chemical potential $\mu_n(T)$ and the entropy density $S(T)$, have been calculated for a set of temperatures between $T = 10$ keV and $T = 100$ keV. We have then evaluated the specific heat according to Eq. (2), by interpolating the entropy density $S(T)$ with cubic splines and numerically differentiating.

For the range of temperatures considered here, $T \ll \varepsilon_F$, where ε_F is the Fermi energy. The specific heat is then approximately given by (ref. [19], p47)

$$c_V(T) \simeq \frac{\pi^2}{3} g(\varepsilon_F) T, \quad (5)$$

where $g(\varepsilon_F)$ is the density of states at the Fermi level. This expression is valid provided i) the density of unbound neutrons ρ_n^G and ε_F are independent of the temperature, ii) the density of states $g(\varepsilon)$ is sufficiently smooth. Pertaining to the first point, we have found numerically that ρ_n^G varies very little so that the neutron evaporation/condensation phenomenon mentioned in Sect. I can be ignored. In a previous paper, we have shown that the density of states in the shallow layers of the crust is far from being smooth at a scale of few keV (see Fig. 6 of Ref. [14]). However, since we consider thermal energies of order 10 keV or more, the variations of the density of states with the energy are expected to be much smaller at this scale as noticed in Ref. [14]. As can be seen in Fig. 1, the neutron specific heat varies almost linearly with T as expected from Eq. (5).

In order to understand more qualitatively our results, we have performed a comparison to several approximations that have been used in the literature.

A. Validity of various approximations

The simplest approximation to the neutron specific heat is to neglect the presence of the nuclear clusters. The specific heat of a Fermi gas is given by

$$c_V^{\text{FG}}(T) = \left(\frac{\pi}{3}\right)^{2/3} \frac{m_n^{\oplus} T}{\hbar^2} (\rho_n^G)^{1/3}, \quad (6)$$

where m_n^{\oplus} is the Skyrme effective mass evaluated at $T = 0$ for the density of the neutron gas ρ_n^G . Note that for the layers we considered, $m_n^{\oplus} \simeq m_n$. As shown in Fig. 1, the specific heat given by (6) is very close to the exact result from the band theory.

This striking result can be understood using the semi-classical Extended-Thomas-Fermi expansion method [20]. At lowest order in \hbar^2 , the neutron specific heat is given by

$$c_V^{\text{TF}}(T) = \left(\frac{\pi}{3}\right)^{2/3} \frac{T}{\hbar^2} \int \frac{d^3\mathbf{r}}{V_{\text{cell}}} m_n^{\oplus}(\mathbf{r}) \rho_n(\mathbf{r})^{1/3}. \quad (7)$$

We have found that higher order corrections in \hbar^2 are negligible. The specific heat (7) shown in Fig. 1 for the three selected layers, is very close to the results of band theory. The small effects of the nuclear lattice can now be easily explained by the small volume fraction occupied by the clusters (typically $\sim 10^{-2} - 10^{-3}$). Indeed in the limit of uniform neutron matter, the Thomas-Fermi specific heat (7) reduces to Eq. (6). A more refined explanation within the full quantum mechanical framework will be given in Sect. II B.

We have also computed the specific heat with the single particle energies ε_{α} obtained in the Wigner-Seitz approximation. Varying the temperature, we have found a small redistribution of the neutron energies ε_{α} close to the Fermi energy. Due to the very large number of neutron states, a small redistribution of energies can have a large impact on the total energy and on the entropy. However, it has been found numerically that the entropy being a smooth function of the occupied and unoccupied states, is much less affected by this redistribution than the total energy. We thus have calculated the specific heat using

$$c_V^{\text{WS}} = T \frac{\partial S^{\text{WS}}}{\partial T} \Big|_V. \quad (8)$$

The entropy density is given by

$$S^{\text{WS}} = -\frac{1}{V_{\text{cell}}} \sum_{\alpha} g_{\alpha} \left[f_{\alpha} \ln f_{\alpha} + (1 - f_{\alpha}) \ln(1 - f_{\alpha}) \right] \quad (9)$$

where g_{α} is the degeneracy of the state α . The specific heat (8) is shown in Fig. 1. Despite non-linear fluctuations due to the redistribution of neutron states, the results are fairly close to those of the band theory. The best agreement is obtained for the layer with the lowest density, as expected from the domain of validity of the Wigner-Seitz method [14],

FIG. 1: (color online) Neutron specific heat divided by the temperature in the three shallow layers calculated with the band theory (solid thick line) and with different approximations: free Fermi gas c_V^{FG} (6) (dotted line), Extended-Thomas-Fermi c_V^{TF} (7) (dashed line), Wigner-Seitz c_V^{WS} (8) (solid line with filled squares) and de Gennes c_V^{DG} (10) (solid line with filled triangle).

We have checked the validity of another approximation, suggested by de Gennes [21] and applied in Ref. [12], consisting in differentiating the entropy (9) with respect to the temperature but assuming that the energies ε_{α} and the chemical potential μ_n (as well as the pairing gaps in superfluid systems) are independent of T . The specific

heat is then given by

$$c_V^{\text{DG}}(T) = \frac{1}{V_{\text{cell}}} \sum_{\alpha} g_{\alpha} f_{\alpha} (1 - f_{\alpha}) \left(\frac{\varepsilon_{\alpha} - \mu_n}{T} \right)^2. \quad (10)$$

As can be seen in Fig. 1, this approximation is valid at very low temperature where the energies and the chemical potential could be taken independent of the temperature but it becomes less and less reliable with increasing temperature.

From the comparison of various approximations to the neutron specific heat, we have found that the Fermi gas model reproduces very well the results of the band theory, while more sophisticated approaches like the Wigner-Seitz or the de Gennes approximations are less accurate. Does it mean that the unbound neutrons are really “free”?

B. Are unbound neutrons really “free”?

The present results on the specific heat together with Eq. (5) indicate that the average density of states are close to that of a Fermi gas (as already noticed in a previous paper, see Fig. 6 and 9 of Ref. [14]). This conclusion is at first sight surprising since the mean field potential is very deep inside the clusters (about -70 MeV). On general grounds, one expects the effects of the nuclear lattice to be negligible whenever the Fermi wavelength of the unbound neutrons $\lambda_F = 2\pi/k_F$ with $k_F = (3\pi^2\rho_n^G)^{1/3}$, is much larger than the lattice spacing. However this condition is not satisfied for the layers we considered. Using the densities ρ_n^G given in Table I, we find $\lambda_F \simeq 40.09, 31.82$ and 25.76 fm for $R_{\text{cell}} = 49.24, 46.33$ and 44.3 fm, respectively. One therefore expects the unbound neutrons to be strongly scattered by the clusters.

If the unbound neutrons were really free as suggested by the results on the specific heat, this would imply that their motion is unaffected by the lattice. It is well-known in solid state physics that the interactions between the conduction electrons and the ionic lattice can be taken into account through renormalizing the mass of the electrons. The motion of an electron in a solid, with a wave vector \mathbf{k} in a band α , can thus be characterized with a dynamical effective mass tensor defined by (ref. [19], p228)

$$\left. \frac{1}{m_e^*} \right|_{ij} = \frac{1}{\hbar^2} \frac{\partial^2 \varepsilon_{\alpha\mathbf{k}}^{(e)}}{\partial k_i \partial k_j} \quad (11)$$

where k_i , $i = 1, 2, 3$ are the Cartesian components of \mathbf{k} and $\varepsilon_{\alpha\mathbf{k}}^{(e)}$ the electron energy. This concept has been extended to low-energy thermal neutrons propagating in crystals and the corresponding effective mass has been experimentally measured in silicon [22]. In the context of neutron star crust, since the number of unbound neutrons per lattice site can be very large, it is more appropriate

to introduce an average effective mass m_n^* defined by [15]

$$m_n^* = \rho_n^G / \mathcal{K}, \quad \mathcal{K} = \frac{1}{3} \sum_{\alpha, i} \int_{\text{F}} \frac{d^3\mathbf{k}}{(2\pi)^3} \frac{1}{\hbar^2} \frac{\partial^2 \varepsilon_{\alpha\mathbf{k}}}{\partial k_i \partial k_i}, \quad (12)$$

where the integral is taken over all occupied states. This dynamical effective mass m_n^* can be equivalently expressed as

$$\frac{1}{m_n^*} = \frac{1}{\rho_n^G} \sum_i \frac{\partial^2 U}{\partial p_{ni} \partial p_{ni}}, \quad (13)$$

where U is the energy density of the moving neutrons in the crust frame and \mathbf{p}_n is the average neutron momentum. This effective mass has implications for neutron star dynamics. For instance it has been shown that a large enough effective mass can trigger a Kelvin-Helmholtz instability which might explain the origin of pulsar glitches [23].

The dynamical effective mass m_n^* has been calculated for the considered layers, using the same numerical method as in Ref. [16]. Results are shown in Table II. If the unbound neutrons were free we would have found $m_n^*/m_n = 1$. However, the dynamical effective mass is much larger than the bare neutron mass $m_n^*/m_n > 1$ indicating that the interactions between the neutrons and the clusters are very strong. In the following, we will explain the apparent contradiction with the results obtained previously for the specific heat.

At the beginning of Sect. II, we have shown that the specific heat varies almost linearly with the temperature (see Fig. 1), as expected from Eq. (5). The density of states $g(\varepsilon_F)$ appearing in Eq. (5) can be expressed as an integral over the Fermi surface \mathcal{S}_F ,

$$g(\varepsilon_F) = \frac{1}{(2\pi)^3 \hbar} \sum_{\alpha} \oint_{\mathcal{S}_F} \frac{d\mathcal{S}}{|\mathbf{v}_{\alpha\mathbf{k}}|}. \quad (14)$$

where $\mathbf{v}_{\alpha\mathbf{k}} = \hbar^{-1} \nabla_{\mathbf{k}} \varepsilon_{\alpha\mathbf{k}}$ is the group velocity of the unbound neutrons. The presence of nuclear clusters leads to the existence of resonances. As a result, the energy bands of unbound states may be locally flat in \mathbf{k} -space thus distorting the Fermi surface [14]. The deformation can be estimated by the ratio ξ_F of the area of the deformed surface to that of the unperturbed Fermi sphere. Therefore, we have $\mathcal{S}_F = \xi_F 4\pi k_F^2$, where by definition $\xi_F = 1$ in the absence of clusters. Numerical calculations show that the nuclear lattice reduces the area of the Fermi surface by more than a factor of 2 in the shallowest layer (see Table II). However since the specific heat is driven by that of a Fermi gas, we can infer from Eq. (14) that in average, the group velocity is changed by the same factor ξ_F compared to that of the Fermi gas.

Likewise the coefficient \mathcal{K} (12) can also be written as an integral over the Fermi surface

$$\mathcal{K} = \frac{1}{3(2\pi)^3 \hbar} \sum_{\alpha} \oint_{\mathcal{S}_F} |\mathbf{v}_{\alpha\mathbf{k}}| d\mathcal{S}. \quad (15)$$

From the previous discussion, it follows that this coefficient is therefore approximately changed by a factor ξ_F^2 . Eq. (12) then implies that $m_n^* \approx m_n/\xi_F^2$. Inspecting Table I shows that the predicted relation between m_n^* and ξ_F is only roughly satisfied because $v_{\alpha\mathbf{k}}$ varies on the Fermi surface. Nevertheless, this analysis in terms of the topology of the Fermi surface explains why the presence of the nuclear clusters has such a strong impact on the motion of the unbound neutrons but not on their specific heat.

III. CONCLUSIONS

Modelling the recently observed thermal relaxation of neutron star crusts requires the knowledge of their thermal properties. In this paper, we have computed the specific heat of the neutron ocean permeating the inner crust at densities below $1.5 \times 10^{12} \text{ g.cm}^{-3}$, by applying the band theory of solids with the Skyrme SLy4 nucleon-nucleon interaction. We have compared the results obtained using different approximations. We have found that for temperatures $T = 10^7 - 10^9 \text{ K}$ relevant to neutron stars, the neutron specific heat is essentially given by that of a Fermi gas. The Thomas-Fermi expression (7) yields nearly undistinguishable results. The specific heat calculated in the Wigner-Seitz approximation agrees reasonably well, while the de Gennes approximation (10) leads to specific heats a factor of 2-3 smaller than those obtained in the band theory.

The results on the specific heat might suggest that the unbound neutrons are not affected by the presence of the nuclear clusters. It is however not true since the dynamical effective mass of the same unbound neutrons is very different from the bare one unveiling strong interactions with the periodic lattice. This apparent paradox can be explained by the fact that the neutron Fermi surface area and the neutron group velocity are both reduced by the same factor in the presence of clusters, leading to a nearly unchanged density of states and specific heat.

TABLE II: For the three shallow layers considered in this paper, are given: the total density (ρ), the dynamical effective mass (m_n^*/m_n) and the reduction factor of the Fermi surface area (ξ_F).
